Ultrasound Evaluation of First Trimester Pregnancy Complications

OBJECTIVES
1. To review normal embryonic development.
2. To identify sonographic features of early pregnancy failure.
3. To identify sonographic features of ectopic pregnancy.

THE EMBRYONIC PERIOD
The embryonic period lasts for 8 weeks after conception or 10 weeks after the last menstrual period, although, clinically, gestational age is assigned according to menstrual dating. This is the period of organogenesis and the time when most malformations arise.

The first sonographic evidence of pregnancy is the gestational sac within the thickened decidua. This sac, which represents the chorionic cavity, is a small anechoic fluid collection surrounded by an echogenic ring that represents trophoblasts and decidua reaction. With transvaginal ultrasound, it is possible to identify the sac by 4 weeks and 3 days gestation when the mean diameter is 2 to 3 mm. The yolk sac is the first structure seen within the gestational sac and, when seen, confirms an intrauterine pregnancy. The yolk sac is seen by transvaginal ultrasound when the mean gestational sac diameter is 5 to 6 mm and should always be visualized when the mean gestational sac diameter is greater than or equal to 8 mm.

The amnion is a thin, rounded membrane surrounding the embryo and is completely enveloped by the thick echogenic

Abstract
Objectives: First, to review normal embryonic development and the sonographic evidence of early pregnancy failure; second, to review sonographic evidence of ectopic pregnancy.
Outcomes: First, prediction of pregnancy failure; second, sonographic identification of ectopic pregnancy.
Evidence: A MEDLINE search and review of bibliographies in identified articles was conducted.
Values: The evidence was reviewed by the Diagnostic Imaging Committee along with the principal authors. A quality of evidence assessment was undertaken as outlined in the report of the Canadian Task Force on the Periodic Health Examination (Table 1).
Benefits, Harms, and Costs: Women presenting with first trimester bleeding may be incorrectly diagnosed with a missed abortion and (or) may be inappropriately reassured about viability. Transvaginal ultrasound provides improved resolution allowing description of early embryonic development characteristics. Improvement in the identification of the sonographic landmarks of normal embryonic development and awareness of the sonographic risk factors of pregnancy failure may lead to more successful management strategies. Diagnosis of suspected ectopic pregnancy often involves an assessment of both hormonal markers and sonographic features. Maternal morbidity and mortality can be reduced with an early diagnosis of ectopic pregnancy.

Recommendations: There is good (class A) evidence that current ultrasound technology can distinguish between normal and abnormal pregnancies in the first trimester. There is good (class A) evidence that transvaginal ultrasound in conjunction with quantitative-HCG can diagnose ectopic pregnancy.

OBJECTIVES
1. To review normal embryonic development.
2. To identify sonographic features of early pregnancy failure.
3. To identify sonographic features of ectopic pregnancy.
chorion. The yolk sac is situated between the amnion and
the chorion. The amnion is thin and difficult to visualize
and best seen when perpendicular to the ultrasound beam.
The amnion grows rapidly during pregnancy and fuses with
the chorion between 12 and 16 weeks of gestation.1,3

The embryo can be identified by transvaginal ultrasound
when as small as 1 to 2 mm in length. At 5 to 7 weeks, both
the embryo and gestational sac should grow 1 mm daily.1
Cardiac activity immediately adjacent to the yolk sac indica-
tes a live embryo but may not be seen until the embryo
measures 5 mm.3,4 From 5.5 to 6.5 weeks, an embryonic
heart rate of less than 100 beats per minute is normal. Dur-
ing the following 3 weeks, there is a rapid increase up to 180
beats per minute.5,6

Table 2 summarizes the features of normal early pregnancy.

**EARLY PREGNANCY FAILURE**

Early pregnancy failure may present with vaginal bleeding
and (or) abdominal pain. Differential diagnoses include
threatened, inevitable, and missed abortion. The latter can
be further subdivided into anembryonic pregnancy
(blighted ovum) or embryonic demise. Other differential
diagnoses include ectopic and molar pregnancy.

Sonographic diagnosis of embryonic demise can be made
when there is no cardiac activity in an embryo greater than 5
mm by transvaginal ultrasound or 9 mm by abdominal
ultrasound.7

Transvaginal sonographic diagnosis of a blighted ovum is
certain when the mean gestational sac diameter exceeds 8
mm without a yolk sac or when the mean gestational sac
diameter exceeds 16 mm without an embryo. Transabdomi-
nally, a gestational sac greater than 20 mm
without a yolk sac or 25 mm without an embryo is diagnos-
tic of a blighted ovum.8

Given the possibility of measurement error, it is prudent to
allow an additional 1 to 2 mm in gestational sac measure-
ment before considering intervention.9 If the gestational sac
is smaller than expected, the possibility of incorrect dates
should always be considered, especially when there is no
pain or bleeding. Under these circumstances, a repeat

A transvaginal scan should be arranged after a 1-week interval.\textsuperscript{10} Figure 1 depicts the sonographic landmarks of early pregnancy failure.

**SONOGRAPHIC FEATURES OF EARLY PREGNANCY FAILURE**

Certain sonographic features predict early pregnancy failure including bradycardia (heart rate less than 85 beats per minute) at greater than 7 weeks of gestation,\textsuperscript{6,11–13} a small sac size relative to the embryo (difference of less than 5 mm between gestational sac and crown/rump length),\textsuperscript{14} enlarged (≥ 5 to 6 mm) 15 or abnormally shaped (crenulated) yolk sac,\textsuperscript{16} and subchorionic hematoma.\textsuperscript{17} Spontaneous loss rate in the presence of a subchorionic hematoma is approximately 9%.\textsuperscript{18} This risk is increased in women older than 35 and in pregnancy less than 8 weeks.\textsuperscript{19}

**CAUSES OF EARLY PREGNANCY FAILURE**

Up to 70% of spontaneous abortions exhibit an abnormal karyotype.\textsuperscript{20,21} Two-thirds will be autosomal trisomies, while the remainder involves monosomy X, structural rearrangements, and other aneuploidies. Only a small percent of early losses related to aneuploidy are due to parental balanced translocations or inversions. Therefore, most women with failed pregnancies and abnormal karyotypes will not have repetitive pregnancy failure.\textsuperscript{22} In the absence of a karyotypic abnormality, pregnancy failure can be associated with luteal phase defects, immunological factors, infection, alcohol, smoking, or lethal genetic abnormalities.

**ECTOPIC PREGNANCY**

The initial diagnostic test in women with suspected ectopic pregnancy is measurement of the serum beta human chorionic gonadotropin (beta-hCG). A negative beta-hCG rules out pregnancy, including ectopic. Ultrasound that demonstrates an intrauterine pregnancy is reassuring because heterotopic pregnancy occurs in only 1:7000 to 1:30 000 of spontaneously conceived pregnancies.\textsuperscript{23} The suspicion of a heterotopic pregnancy should be higher after assisted reproduction techniques because the incidence in this circumstance is up to 1%.\textsuperscript{24,25} The diagnosis of an intrauterine pregnancy involves visualizing a gestational sac within the endometrial cavity showing an embryo or yolk sac or demonstrating a double echogenic ring.\textsuperscript{26} An intrauterine fluid collection without these characteristics may be a pseudogestational sac. If an intrauterine pregnancy is not demonstrated, the differential diagnosis includes inaccurate dates, complete abortion, and ectopic pregnancy. The sonographic appearance of an ectopic is varied. There may be a simple adnexal cyst, complex adnexal mass, tubal ring, free fluid in the adnexa-cul de sac, a live extraterine fetus, or an empty uterus with no other sonographic findings.\textsuperscript{27,28}
With the clinical suspicion of ectopic, a normal scan or the presence of a simple cyst carries a low probability of ectopic (5%), while the probability is above 90% with a complex adnexal mass or a tubal ring. A live extrauterine embryo is diagnostic of an ectopic. Isolated free fluid in the pelvis is rarely the only sonographic finding. Doppler waveforms from the peritrophoblast have been shown to demonstrate low impedance flow, while colour Doppler may demonstrate an ectopic as a sonographic ring. Doppler does not add clinically useful information when the sonographic features indicate a high or low likelihood of ectopic but may provide important information when other sonographic findings lead to a diagnostic dilemma. For example, with a complex adnexal mass, the finding of low impedance Doppler waveform or a ring on colour Doppler may more strongly suggest an ectopic pregnancy.

High-resolution ultrasound and the quantitative level of serum beta-hCG are complementary. Most ectopic pregnancies are associated with a disproportionately high level of beta-hCG relative to the size of any intrauterine fluid collection. Failure to detect an intrauterine gestational sac when the beta-hCG values exceed a discriminatory level indicates a high risk of ectopic pregnancy. Most ultrasound laboratories use beta-hCG levels between 1000 to 2000 mIU/ml as the threshold above which an intrauterine gestational sac should be visualized by vaginal ultrasound. With some ectopics, the hCG will show an abnormally low rise, and in this circumstance, a search for ultrasound features associated with ectopic pregnancies should be made. Table 3, adapted from Yao et al., simplifies the diagnosis of ectopic pregnancy.

Table 3. Diagnosis of asymptomatic tubal ectopic pregnancy

| Possible ectopic pregnancy | Serum β-hCG level > 1500 mIU/ml |
| Probable ectopic pregnancy | Absence of intrauterine pregnancy on transvaginal ultrasound |
| Diagnosis of ectopic pregnancy | Adnexal mass on transvaginal ultrasound |
| | Absence of intrauterine pregnancy on transvaginal ultrasound |
| | Gestational sac inside fallopian tube on transvaginal ultrasound |

Transabdominally, a gestational sac greater than 20 mm without a yolk sac or 25 mm without an embryo is diagnostic of a blighted ovum.

2. Given the possibility of measurement error, it is prudent to allow an additional 1 to 2 mm in gestational sac measurement before intervention. If the gestational sac is smaller than expected, the possibility of incorrect dates should always be considered, especially when there is no pain or bleeding. Under these circumstances, a repeat transvaginal scan should be arranged after an interval of at least one week.

3. Failure to detect an intrauterine gestational sac by transvaginal ultrasound when the beta-hCG value exceeds a discriminatory level (1000 to 2000 mIU/ml) indicates an increased risk for ectopic pregnancy. With a complex adnexal mass or a tubal ring, the probability of ectopic pregnancy is high, while a live extrauterine embryo is diagnostic of an ectopic.
